

# User Interfaces

## Lecture 19

### Cocoa: Mouse and Keyboard Events

Hamza Bennani

hamza@hamzabennani.com

September 18, 2018

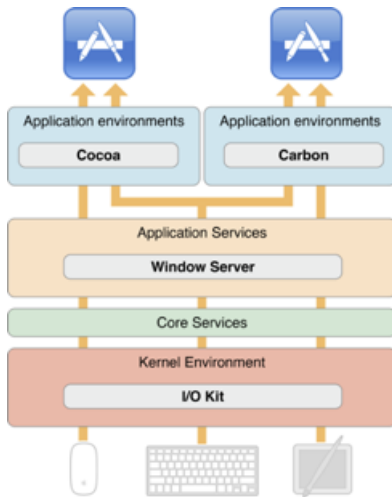

# Last Lecture

Where did we stop?

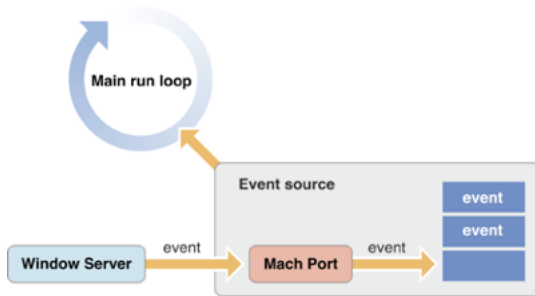

# Events

- ▶ Events get filtered into a queue by MacOS X
- ▶ Some events never reach the application, like ?, or ?
- ▶ The active application processes events one at a time from the queue

# The event loop

- ▶ Events are encoded as NSEvent objects and put into a queue
  - ▶ The active application takes events from the queue and processes them
  - ▶ NSEvent contains information such as location, time, etc . . .

# Where events go?

## Mouse Event

## Key Event

- ▶ The active application NSApp object issues a sendEvent: message to the active window
  - ▶ A mouse event is forwarded to the view where the mouse is pointing
  - ▶ A key event is forwarded to the window's "responder chain"

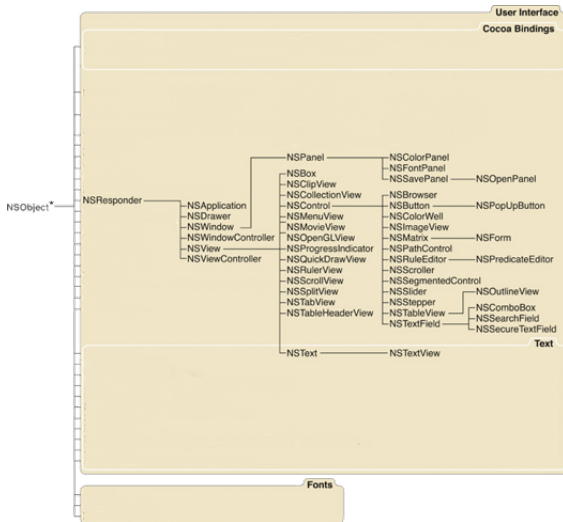

# NSEvent

- ▶ Events are passed to handling methods as NSEvent objects
- ▶ For mouse events, information includes:
  - ▶ locationInWindow
  - ▶ modifierFlags (NSShiftKeyMask, NSControlKeyMask, ...)
  - ▶ timestamp
  - ▶ window - window where event occurred
  - ▶ clickCount - number of mouse clicks
  - ▶ pressure - tablet
  - ▶ deltaX, deltaY - change in position
- ▶ For key events, information includes:
  - ▶ characters - an NSString object with typed keys
  - ▶ isARepeat - YES or NO regarding whether key is held down
  - ▶ keyCode - actual key that user pressed
  - ▶ modifierFlags - same as mouse modifierFlags

# NSResponder

- ▶ ... is an abstract class that dispatches received NSEvents to methods corresponding to various mouse and keyboard events
- ▶ All event-handling methods are declared in NSResponder. The following classes inherit from it:
  - ▶ NSWindow - so all windows
  - ▶ NSView - so almost everything that's in the window, including NSControl objects, such as buttons, etc.
  - ▶ NSApplication
  - ▶ ... and even controllers: NSWindowController, NSViewController
- ▶ You can override NSResponder messages that you want to handle in your custom view

# NSResponder Hierarchy

\*Class defined in the Foundation framework

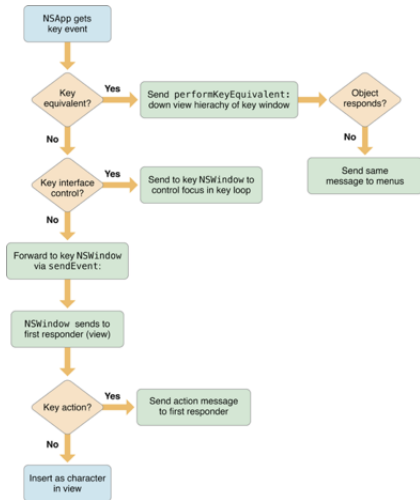

# Responding to Mouse Events

- ▶ Methods: `mouseDown`, `mouseUp`, `mouseDragged`, `mouseEntered`, `mouseExited`, `mouseMoved`, `scrollWheel`
  - ▶ Note: certain rules apply to mouse events, e.g., mouse-up must be preceded by mouse-down, mouse-dragged must occur between mouse-down and mouse-up, etc.
- ▶ The methods get passed an argument of `NSEvent` type, which responds to methods that provide information about the mouse event:
  - ▶ `clickCount` - number of clicks that occurred
  - ▶ `windowLocation` - location where mouse was clicked
  - ▶ Methods to obtain scroll wheel information

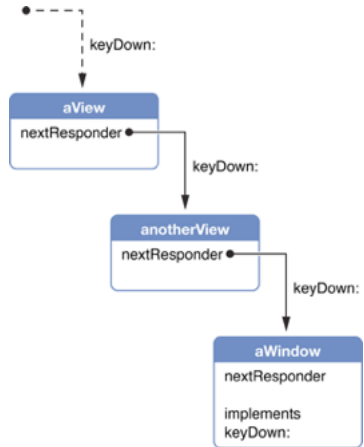

# Responding to Key Events

- ▶ Key events are more complicated than mouse events, because they lack a target location
- ▶ Certain key combinations go straight to menu bar (e.g., command-Z), others to operating system (e.g., Mission Control)

# The Responder Chain

- ▶ Key events are processed using the responder chain
  - ▶ A message is initially passed to the first responder
  - ▶ If the first responder does not accept the message, it is passed to the nextResponder
- ▶ Responder chain implements the chain of responsibility design pattern
- ▶ The responder chain is implemented in NSResponder

# The Responder Chain

# Window Types

- ▶ Assumption: in any application, even if it is multi-window, there is only one window with the user's focus. Therefore, the windows are categorised into the following types:
  - ▶ Main window - the window that the user is working in currently
  - ▶ Key window - the window that accepts user's input
  - ▶ Inactive window - all other windows
  - ▶ The main and key windows often are the same window - common exception are window panels for opening, saving, preferences, etc., which take input focus, but are not main windows
  - ▶ The NSApplication singleton has separate references to the main and key windows (although often these refer to the same window object)

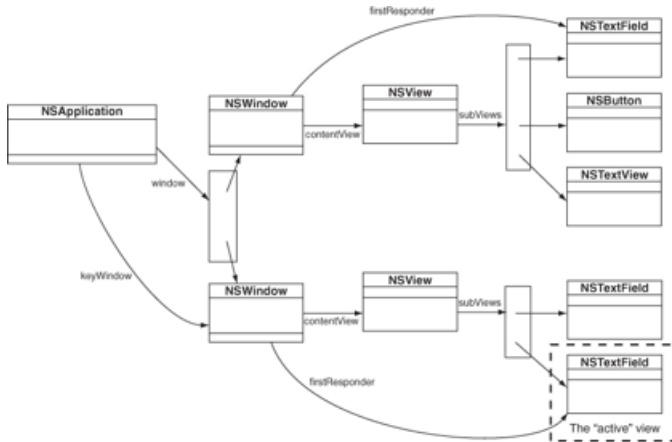

# First Responder

## Window Change

- ▶ Each window has a first responder outlet
  - ▶ The active window's first responder gets key events
- ▶ The inner workings of `NSApplication` update its `keyWindow` outlet to correspond to the window currently selected by the user
  - ▶ A mouse click on an inactive window does not send an event to that window, it just changes that window to become the `keyWindow`

# First Responder

## Window Change

# Initial First Responder

- ▶ What does the first responder outlet point to just after a window is created?
  - ▶ Initial first responder is the element that window's first responder points to by default
- ▶ You can set the initial first responder:

```
import Cocoa

class OurWindowController: NSWindowController {
    @IBOutlet weak var view1: NSView!
    @IBOutlet weak var view2: NSView!

    convenience init() {
        self.init()

        self.window?.initialFirstResponder = view1
    }
}
```

# First Responder

## View Change

- ▶ The inner workings of the NSWindow object updates its firstResponder outlet to reference the currently selected view
- ▶ The first responder for the application is the object pointed to by the firstResponder reference of the key Window

When the user tabs from one text field to the next, the text field that would become key is asked whether it accepts first-responder status.

If it accepts, the original first responder is asked whether it will resign first-responder status.

If it resigns, the first-responder outlet is changed, and the new first responder is sent becomeFirstResponder.

# First Responder Placeholder

- ▶ In Interface Builder there's a placeholder object that stands in for an arbitrary first responder
- ▶ You can set custom action methods for this placeholder
- ▶ You can connect target actions from window elements to the first responder placeholder
- ▶ At run-time, when the window element is selected, it sends an action to the object that happens to be the current first responder

# NSControl

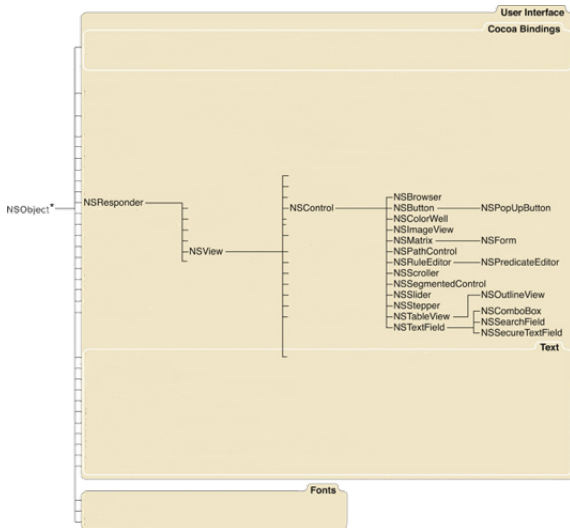

- ▶ Object that inherits from NSResponder
- ▶ It contains an NSCell object, which has a reference to target object and action selector
- ▶ Buttons, check boxes, and many other UI controls inherit from NSControl
  - ▶ Each different control overrides selected NSResponder methods to redirect the event to the action selector of the target object (if target and action have been set)
  - ▶ Example: NSButton class overrides mouseDown event invoking the action method of its corresponding target
- ▶ Target and action values can be set through Interface Builder
  - ▶ We have seen how to do this in Lecture 15/16

# NSControl

- ▶ Target and action values can also be set programmatically
- ▶ This example modifies the ViewController of a storyboard
- ▶ myB is an NSButton without an IBAction set in the Xcode IB

```
import Cocoa
class ViewController: NSViewController {
    @IBOutlet weak var label: NSTextField!
    @IBOutlet weak var myB: NSButton!
    var count: Int = 0
    override func viewDidLoad() {
        super.viewDidLoad()
        myB.target = self
        myB.action = #selector(ViewController.clickAction(sender:))
    }
    @IBAction func clickAction(sender: AnyObject) {
        count += 1
        label.stringValue = "Click count \(count)"
    }
}
```

# NSControl Hierarchy

\*Class defined in the Foundation framework

# Things To Watch out for?!

- ▶ The pre-made objects in the Cocoa's object library that inherit from `NSResponder` override various methods to implement specific behaviour for the type of interface they represent
- ▶ Example1:
  - ▶ `NSButton` (which is an `NSControl`), overrides `mouseDown:` method to execute an action of the corresponding target
  - ▶ If you extend `NSButton` and override `mouseDown:` method, you may disable the target action functionality
- ▶ Example2:
  - ▶ `NSView` `becomeFirstResponder:` returns `NO` by default
  - ▶ Override method in your custom view to return `YES` if you want the view to become a part of the responder chain

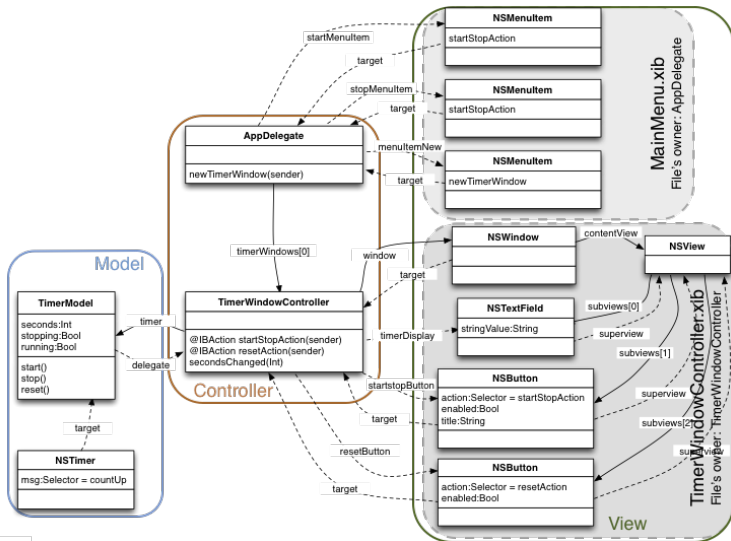

# Summary

We examined how Cocoa applications process events and introduced some concepts that make dealing with events in your program easier

- ▶ NSEvent - object representing an event with all information about it
- ▶ NSResponder - an abstract class that sorts out the events it receives into more readable methods corresponding to mouse and keyboard events
- ▶ NSControl - an abstract class that contains a reference to a target and action, which can be triggered after an event
- ▶ First responder - reference to an object in a window that has focus
- ▶ First responder placeholder - object in Interface Builder with custom actions to which controls can be connected: at runtime, whenever the corresponding control event triggers an action, it gets sent to the target that happens to be the current first responder
